1 Introduction and learning objectives

Monetarism, most strongly associated with Milton Friedman, reasserted the centrality of money in macroeconomic fluctuations and inflation. The core claim is that money growth is a key driver of nominal spending in the short run and the price level over longer horizons, and that policy should be guided by stable, rule-like principles rather than discretionary fine tuning.

This chapter examines the main monetarist propositions and their relevance for modern monetary policy:

1. The quantity-theory position and the monetarist claim that money matters, with a focus on the stability (or not) of velocity.
2. The monetarist macro model of dichotomy and money neutrality (labour market → output → money market → prices) and how it rationalises the proposition that money has no long-run real effects.
3. The short-run non-neutrality logic via money illusion and expectations adjustment, connected to the Phillips curve controversy and the natural-rate hypothesis.
4. The distinction between nominal and real interest rates (Fisher equation), and why persistent inflation affects nominal interest rates (the Fisher effect) even when long-run real rates are pinned by real forces.
5. The logic of inflationary equilibria and hyperinflation, using Cagan-style definitions, fiscal-monetary linkages, and historical evidence on stabilisations.
6. A modern evidence-based discussion: Japan's long zero lower bound (ZLB) period, post-2008 QE, negative rates, and COVID-era money growth, showing where monetarist predictions perform well and where institutional realities complicate simple money-growth targeting.

2 Intellectual context: what Friedman was responding to

In his presidential address “The Role of Monetary Policy,” Friedman characterises the mid-20th-century swing in professional opinion: from early confidence in central-bank fine tuning (1920s), to the belief that monetary policy is a string (early Depression-era aphorisms), to the dominance of Keynesian analysis and fiscal policy in the postwar period, and then back toward renewed belief in monetary potency after inflationary experience and reinterpretations of the Great Depression.

Friedman's narrative frames monetarism as a historical research programme: (i) reinterpretations of monetary history, (ii) restatement of the quantity theory in a modern portfolio/asset-demand language, and (iii) derivation of policy principles that acknowledge lags and uncertainty.

3 The quantity theory position and monetarist propositions

At its simplest, the quantity theory starts from the accounting identity:

$$MV \equiv PY,$$

where M is a monetary aggregate, V velocity, P the price level, and Y real output. Monetarism becomes a substantive theory when it adds empirical claims (or approximations) such as:

- velocity is sufficiently stable (or at least predictable conditional on a small set of variables), implying a stable relationship between money growth and nominal spending growth;
- in the long run, money is neutral (changes in the level of money affect nominal variables like P and nominal wages, not real output);
- in the short run, money can be non-neutral because wages/prices adjust with lags, generating transitional output and employment effects.

An institutional summary by the IMF documents why monetarism's prominence fell when velocity became unstable amid deregulation and financial innovation, an empirical point that remains central to understanding monetary policy frameworks ([Jahan and Papageorgiou, 2014](#)).

4 A canonical monetarist macro model: dichotomy and neutrality

The canonical monetarist model can be written as a four-block system, which clarifies the dichotomy.

Labour market (real wage determination). Let real wage be w/P . Labour supply and demand depend on the real wage:

$$N^s = N^s\left(\frac{w}{P}; \psi\right), \quad N^d = N^d\left(\frac{w}{P}; K\right)$$

with equilibrium employment N^* solving $N^s = N^d$. Natural unemployment follows from labour force L : $u^* = L - N^*$ (or as a rate $u^* = 1 - N^*/L$).

Production function (real output supply). With capital K and equilibrium labour N^* :

$$Y^s = F(K, N^*).$$

Real output is therefore supply-determined in the long-run classical/monetarist benchmark.

Goods market (IS-style relation). Aggregate demand depends on the nominal interest rate i and fiscal instruments:

$$Y^d = Y^d(i, G, T),$$

with $\partial Y^d / \partial i < 0$, $\partial Y^d / \partial G > 0$, $\partial Y^d / \partial T < 0$ as standard comparative statics. In the classical benchmark, i is a relative price in real terms that equilibrates saving and investment (loanable funds), but Friedman's macro narrative emphasises that money can shift spending and thus nominal income when prices are sticky or when monetary shocks occur.

Money market / money demand (quantity-theory money demand). A simple transactions-style demand for money is:

$$M^d = k \cdot P \cdot Y,$$

where k is the desired money-income ratio (inverse velocity). In long-run equilibrium with a given $Y = Y^s$, the money market pins down P :

$$P = \frac{M}{kY^s}.$$

Thus the model delivers a classical dichotomy: real equilibrium (N^*, Y^s) is determined outside the monetary block; the monetary block determines nominal magnitudes.

Figure 1 illustrates how N^* is determined by the real wage w/P . **Figure 2** shows the flow from the labour market through production and demand to the AD-AS framework, with vertical long-run aggregate supply and aggregate demand derived from $Y = (1/k)(M/P)$.

Labour Market Equilibrium

Figure 1: Labour market equilibrium: natural employment N^* is pinned by the intersection of labour supply $N_s(w/P)$ and labour demand $N_d(w/P)$.

5 Comparative statics tables and policy interpretation

5.1 Table 1: One-off increase in money level M (short run vs long run)

The following table illustrates the comparative statics of monetary expansion, showing long-run neutrality and short-run transitional effects under money illusion and sticky nominal wages.

AD-AS: Monetarist Long-Run Equilibrium

Figure 2: Aggregates demand and supply in the monetarist model: long-run aggregate supply is vertical at Y^* . An increase in money shifts AD rightward, raising prices but not output.

Variable	Short run (prices/wages not fully adjusted; money illusion/stickiness)	Long run (fully adjusted nominal wages/prices; classical/monetarist benchmark)
M	Up (policy/monetary expansion)	Up (permanent level shift)
P	Tends to rise, but not necessarily one-for-one immediately	Rises approximately one-for-one with M (neutrality)
w (nominal wage)	Adjusts sluggishly; may rise less than P initially	Rises proportionately with P so that w/P returns to equilibrium
w/P (real wage)	May temporarily fall if P rises faster than $w \rightarrow$ firms hire more	Returns to labour-market equilibrium
N, Y	May temporarily rise if firms respond to lower perceived real wage	Returns to N^*, Y^s
Unemployment u	May temporarily fall (below u^*)	Returns to u^*
Key mechanism	Misperception/adjustment lags $\rightarrow$ short-run non-neutrality	No money illusion + flexible prices $\rightarrow$ long-run neutrality

5.2 Table 2: Permanent increase in money growth μ (super-neutrality benchmark and Fisher effect)

Let money growth be $\mu \equiv \Delta M/M$, inflation $\pi \equiv \Delta P/P$, and real output growth $g \equiv \Delta Y/Y$. From $MV = PY$, under stable V :

$$\pi \approx \mu - g.$$

With expected inflation π^e , the Fisher relation can be written:

$$i \approx r + \pi^e.$$

Proposition	Prediction (benchmark)	What changes in modern data-rich policy regimes
Money growth and inflation	Higher long-run $\mu \rightarrow$ higher long-run π (unless V falls persistently)	Velocity instability can weaken money-nominal GDP links, complicating money-growth targeting
Nominal vs real rates	Higher $\pi^e \rightarrow$ higher i (Fisher effect) with r pinned by real forces in long run	At or near the ZLB, i may be constrained; term premia and longer yields become policy targets via QE
Super-neutrality	Changes in μ do not permanently change Y , N , u (benchmark super-neutrality)	In practice, regime shifts, financial frictions, and policy credibility can generate persistent real effects in transitions

6 Money illusion, the Phillips curve, and the natural-rate hypothesis

The narrative linking short-run monetary expansions to temporary unemployment reduction is consistent with expectations-augmented Phillips curve logic: observed inflation/unemployment correlations reflect short-run nominal rigidities or misperceptions, but do not deliver a stable long-run trade-off. Friedman’s 1968 address makes this a central argument by insisting monetary policy cannot peg unemployment below its natural benchmark except temporarily, because expectations adjust ([Friedman, 1968](#)).

The key historical sequence is:

- Phillips ([1958](#)) documented a nonlinear empirical relationship between unemployment and wage inflation for the UK over a long historical sample.
- Samuelson and Solow (1960) interpreted this relationship in a policy context (later debates question how menu-like their intended interpretation was).
- Phelps ([1967](#)) provided an explicit expectations-based framework, arguing that inflation expectations affect unemployment dynamics and that systematic policy cannot permanently trade inflation for unemployment.
- Friedman ([1968](#)) popularised the policy conclusion: attempts to hold unemployment below its natural level lead to accelerating inflation, not a stable improvement in real activity.

In accessible final-year notation, an expectations-augmented Phillips curve can be written as:

$$\pi_t = \pi_t^e - \alpha(u_t - u^*) + \nu_t,$$

where $\alpha > 0$ and ν_t is a supply/markup disturbance. Under adaptive expectations $\pi_t^e \approx \pi_{t-1}$, disinflation implies transitional unemployment (sacrifice ratio), a key point in the monetarist critique of discretionary stabilization.

7 The policy message: rules, lags, and skepticism about fine tuning

A signature monetarist policy conclusion is that activist discretionary policy is likely to destabilize because policy operates with long and variable lags. This motivates the constant money-growth rule (often presented as the $k\%$ rule): target money growth at a stable constant rate

roughly consistent with long-run real output growth (or desired inflation). Modern central banking rarely implements the rule in its original form, but it remains a benchmark in rules-versus-discretion debates and in the design of robust frameworks.

8 Monetarism at the zero lower bound (ZLB), effective lower bound (ELB), and with QE/negative rates

Modern monetary policy must address an apparent tension: monetarism emphasises targeting money growth, but central banks predominantly implement policy through interest-rate setting, supported by balance-sheet tools when rates hit lower-bound constraints. Here, the **zero lower bound (ZLB)** refers to the benchmark case where nominal policy rates cannot fall below zero, while the **effective lower bound (ELB)** is the practical limit faced by a central bank once cash, institutional frictions, and transmission constraints are taken into account. In practice, the distinction between money and rates is not a binary choice: interest-rate policy is implemented through operations that affect the central bank balance sheet and monetary aggregates; conversely, balance-sheet policies matter by altering asset supplies, term premia, and risk premia.

Example: the COVID-era money surge (US and euro area).

- In the US, the Fed's H.6 release shows a dramatic jump in M2 during early 2020, illustrating that money aggregates can move rapidly in crisis conditions ([Governors of the Federal Reserve System, 2020](#)).
- In the euro area, the ECB documented a marked acceleration in broad money growth in March 2020 and linked it to emergency liquidity needs and precautionary money holding amid pandemic uncertainty ([Bank, 2020a, 2020b](#)).

This observation illustrates a key point: monetarists emphasised that velocity stability is crucial. In crises, velocity can shift sharply as liquidity preference rises, so money growth alone does not map mechanically into inflation in the short run.

9 Nominal and real interest rates in practice

The nominal versus real interest rate discussion connects the Fisher equation to two sets of contemporary facts:

1. At the ZLB, the Fisher relation does not disappear, but nominal rates can be constrained, shifting adjustment into expected inflation, real rates, and longer-term yields.
2. Negative policy rates show that the lower bound is not literally zero for policy rates, but practical constraints (cash, retail deposit rate rigidities, and bank profitability concerns) matter ([Bank for International Settlements, 2016](#); [Borio and Zabai, 2016](#)).

Central Bank Policy Rate Corridor with Negative Rates

Figure 3: Central bank policy rate corridor with negative rates: policy facility rate (lower bound) can be negative, but retail deposit rates often remain constrained near zero.

10 Inflationary equilibria: money demand, fiscal dominance, and the high-inflation trap

Inflationary equilibria can be analysed using a simplified Cagan-style framework consisting of (i) a semi-log money demand and (ii) a government budget constraint implying seigniorage finance.

A standard high-inflation money demand specification is:

$$\frac{M}{P} = Ae^{-\alpha\pi^e}, \quad \alpha > 0,$$

so higher expected inflation reduces real money demand. Combine this with a government need for seigniorage (money creation revenue) to finance deficits when other financing is limited. A key pedagogical point is nonlinearity: when inflation rises, the tax base (real balances) can shrink rapidly, so generating a given amount of seigniorage may require ever higher inflation, potentially producing unstable dynamics or multiple equilibria in some models.

11 Hyperinflation: definition, evidence, and endings

Definition (Cagan criterion). Hyperinflation begins when monthly inflation first exceeds 50% and ends when it falls below 50% for at least a year ([Fund, 2007](#)).

Empirical regularity: fiscal regime change and credible stabilisation. Sargent’s classic “Ends of Four Big Inflations” argues that dramatic hyperinflations ended alongside major fiscal regime shifts and reforms that changed expectations about future money creation ([Sargent, 1982](#)).

Hyperinflation is significant because it exemplifies the starkest money–prices relationship and provides direct historical evidence of monetisation of fiscal deficits.

12 Comparative table: post-1990 policy episodes, tools, and outcomes

The following table summarises post-1990 monetary episodes and their policy responses.

Illustrative episode details in the table are drawn from official central bank releases/timelines and well-known empirical studies, including the BoJ policy chronology, Bank of England announcements and QE evidence, ECB press releases on negative rates and PEPP, and the New York Fed LSAP staff report ([England, 2009](#); [Joyce *et al.*, 2010](#); [Gagnon *et al.*, 2010](#); [Bank, 2014, 2020a](#); [Japan, 2026](#)).

Episode	Monetary-policy constraint	Main tools used	Scale/timing (illustrative, official)	Evidence on financial conditions/outcomes
Japan (late 1990s-2000s; long ZLB era)	Persistent low inflation/deflation; policy rates near zero	ZIRP; QE (current account balances target); later QQE	BoJ timeline: ZIRP (Feb 1999-Aug 2000); QE (Mar 2001-Mar 2006) with explicit balance targets (e.g., ~JPY5tn initial current account balance target)	Illustrates liquidity preference/velocity shifts and the difficulty of rekindling inflation
UK (GFC response, 2009-2010)	Bank Rate at effective lower bound	QE via gilt purchases financed by reserves	MPC March 2009: Bank Rate cut to 0.5% and GBP75bn purchases; by Feb 2010 purchases reached GBP200bn; BoE estimates gilt yields down about 100bp	BoE research attributes significant yield compression to QE; macro effects exist but are uncertain and model-dependent

Episode	Monetary-policy constraint	Main tools used	Scale/timing (illustrative, official)	Evidence on financial conditions/outcomes
Euro area (negative rates + PEPP, 2014-2024)	Low inflation + fragmentation risk; ELB dynamics	Negative deposit facility rate; asset purchases APP/PEPP; TLTROs	ECB cut deposit facility rate to -0.10% effective 11 June 2014; PEPP launched at EUR750bn (Mar 2020), expanded to EUR1,850bn; PEPP+APP estimated to reduce GDP-weighted 10-year yield about 45bp in 2020	ECB documents term-premium compression and transmission support; negative rates transmit unevenly
US (ZLB and LSAPs, 2008-2010; COVID and beyond)	Fed funds at 0-25bp (Dec 2008), later ELB again in 2020	LSAP/QE; forward guidance; liquidity facilities	NY Fed SR441: purchases announced Nov 2008; expanded March 2009 to total up to USD1.75tn; designed to lower private borrowing rates by reducing term/risk premia	NY Fed analysis finds meaningful reductions in longer-term rates, mainly through lower term/risk premia rather than expectations of future short rates

13 Policy implications: what survives from Friedman's monetarism today

Core propositions and durable insights: The broad long-run propositions are consistent with standard textbook treatments and the monetarist literature ([Friedman, 1968](#); [Lewis and Mizen, 2000](#)).

- Inflation cannot persist indefinitely without accommodating monetary expansion; monetary conditions matter for nominal aggregates over longer horizons.
- Policy should be evaluated under lags and uncertainty; discretionary fine tuning can be destabilising when transmission is slow and variable.
- Asset purchases and balance-sheet tools can matter at the ZLB by lowering term premia and risk premia, consistent with portfolio-balance mechanisms.

Limits, qualifications, and modern extensions:

- Stable velocity is not guaranteed; financial innovation and regulation shape money demand and can destabilise money-nominal GDP links, reducing the practicality of money-growth targeting.
- Money supply is not a single object; it depends on definitions (M0/base vs M1/M2/M3) and on the banking system's credit creation, which is why modern central banks focus on interest-rate implementation and broader indicator sets.

14 Problem questions

1. **Derivation and interpretation.** Starting from $MV \equiv PY$, derive $\pi \approx \mu + v - g$ where v is velocity growth. Under what assumptions does this collapse to $\pi \approx \mu - g$? What happens when V becomes unstable?
2. **Neutrality table.** Using Table 1 above, explain precisely which assumptions deliver long-run neutrality. Then propose one realistic friction (wage stickiness, imperfect information, financial frictions) that generates the short-run deviations. Anchor your discussion in Friedman's warnings about policy overreach.
3. **Natural rate and expectations.** Write an expectations-augmented Phillips curve and show algebraically why a permanent attempt to hold $u < u^*$ generates accelerating inflation under adaptive expectations. Use Friedman (1968) and Phelps (1967) as your anchors.
4. **Nominal vs real interest rates.** From the Fisher equation $i = r + \pi^e$, discuss what each term means and how negative policy rates complicate measurement and transmission. Use BIS evidence on negative-rate implementation to discuss one channel that behaves differently at negative rates.
5. **LSAP/QE mechanism.** Explain the portfolio-balance channel in your own words and distinguish term-premium effects from expected-future short-rate effects. Why does this distinction matter for whether QE proves monetarism?
6. **Hyperinflation essay.** Using the IMF definition and Sargent's evidence, explain why hyperinflation is typically linked to fiscal regimes and why stabilisation often requires credible fiscal reform. How does this relate to monetarist emphasis on money growth?
